Bitcoin Consensus Algorithm

Consensus algorithm (simplified)

1. New transactions are broadcast to all nodes
2. Each node collects new transactions into a block
3. In each round a random node gets to broadcast its block
4. Other nodes accept the block only if all transactions in it are valid (unspent, valid signatures)
5. Nodes express their acceptance of the block by including its hash in the next block they create

Incentive for miners

Incentive 1: block reward

Creator of block gets to

- include special coin-creation transaction in the block
- choose recipient address of this transaction

Value is fixed: currently 12.5 BTC, halves every 4 years

Block creator gets to “collect” the reward only if the block ends up on long-term consensus branch!

Incentive 2: transaction fees

Creator of transaction can choose to make output value less than input value

Remainder is a transaction fee and goes to block creator

Purely voluntary, like a tip

Proof of Work

Consensus protocol used by Bitcoin

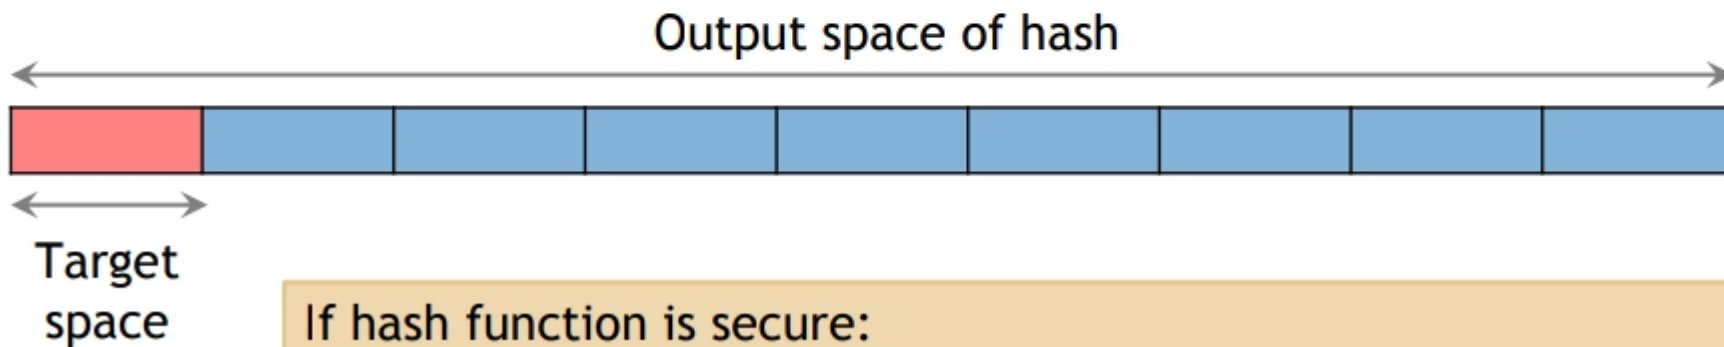

Equivalent views of proof of work

1. Select nodes in proportion to computing power
 1. Let nodes compete for right to create block
 1. Make it moderately hard to create new identities
- 

Hash puzzles

To create block, find nonce s.t.
 $H(\text{nonce} \parallel \text{prev_hash} \parallel \text{tx} \parallel \dots \parallel \text{tx})$ is very small

If hash function is secure:
only way to succeed is to try enough nonces until you get lucky

PoW property 1: difficult to compute

As of Aug 2014: about 10^{20} hashes/block

Only some nodes bother to compete —
miners

PoW property 2: parameterizable cost

Nodes automatically re-calculate the target every two weeks

Goal: average time between blocks = 10 minutes

PoW property 3: trivial to verify

Nonce must be published as part of block

Mining economics

If mining reward (block reward + Tx fees)	>	hardware + electricity cost	→	Profit
--	---	--------------------------------	---	--------

Complications:

- fixed vs. variable costs
- reward depends on global hash rate

How Wallets Work

Signatures: Private & Public Keys

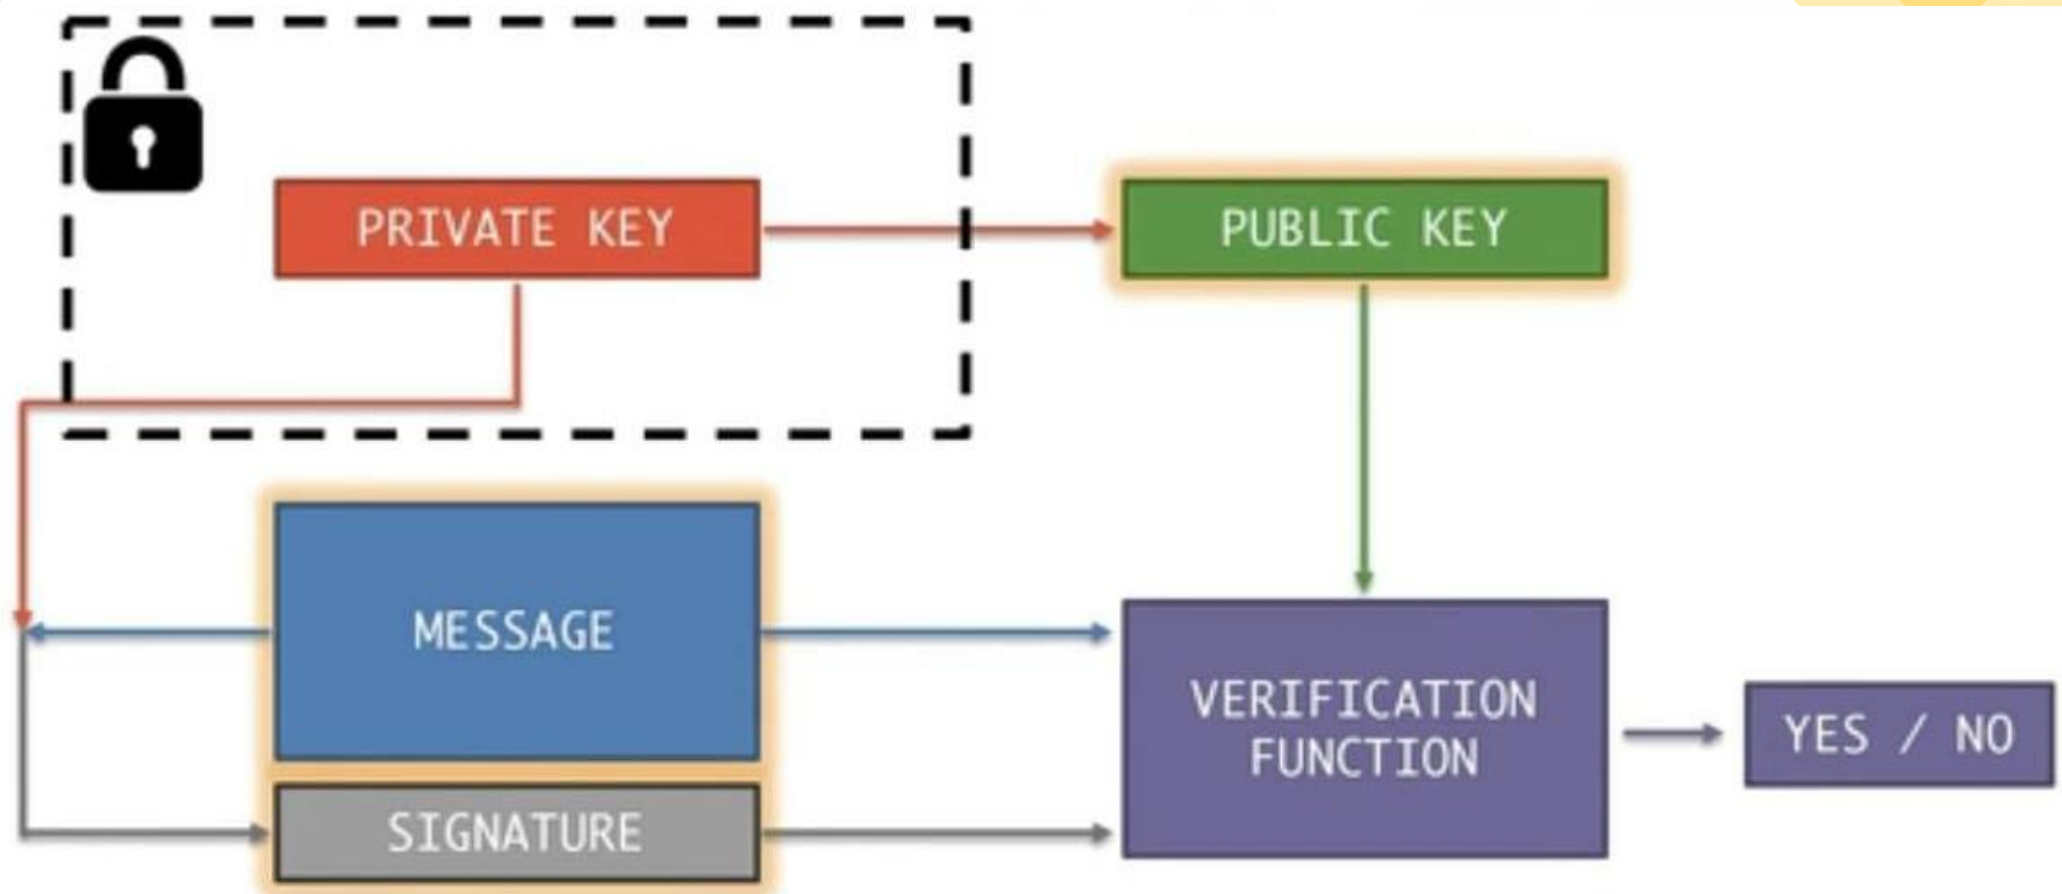

What we want from signatures

Only you can sign, but anyone can verify

Signature is tied to a particular document
can't be cut-and-pasted to another doc

API for digital signatures

$(sk, pk) := \text{generateKeys}(\text{keysize})$

sk: secret signing key

pk: public verification key

$\text{sig} := \text{sign}(sk, \text{message})$

$\text{isValid} := \text{verify}(pk, \text{message}, \text{sig})$

can be
randomized
algorithms

<https://tools.superdatascience.com/blockchain/public-private-keys/keys>

Requirements for signatures

“valid signatures verify”

`verify(pk, message, sign(sk, message)) == true`

“can’t forge signatures”

adversary who:

knows pk

gets to see signatures on messages of his choice

can’t produce a verifiable signature on another message

Bitcoin uses ECDSA standard

Elliptic Curve Digital Signature Algorithm

relies on hairy math

will skip the details here --- look it up if you care

good randomness is essential

foul this up in generateKeys() or sign() ?

probably leaked your private key

GAME
OVER

Decentralized identity management

anybody can make a new identity at any time
make as many as you want!

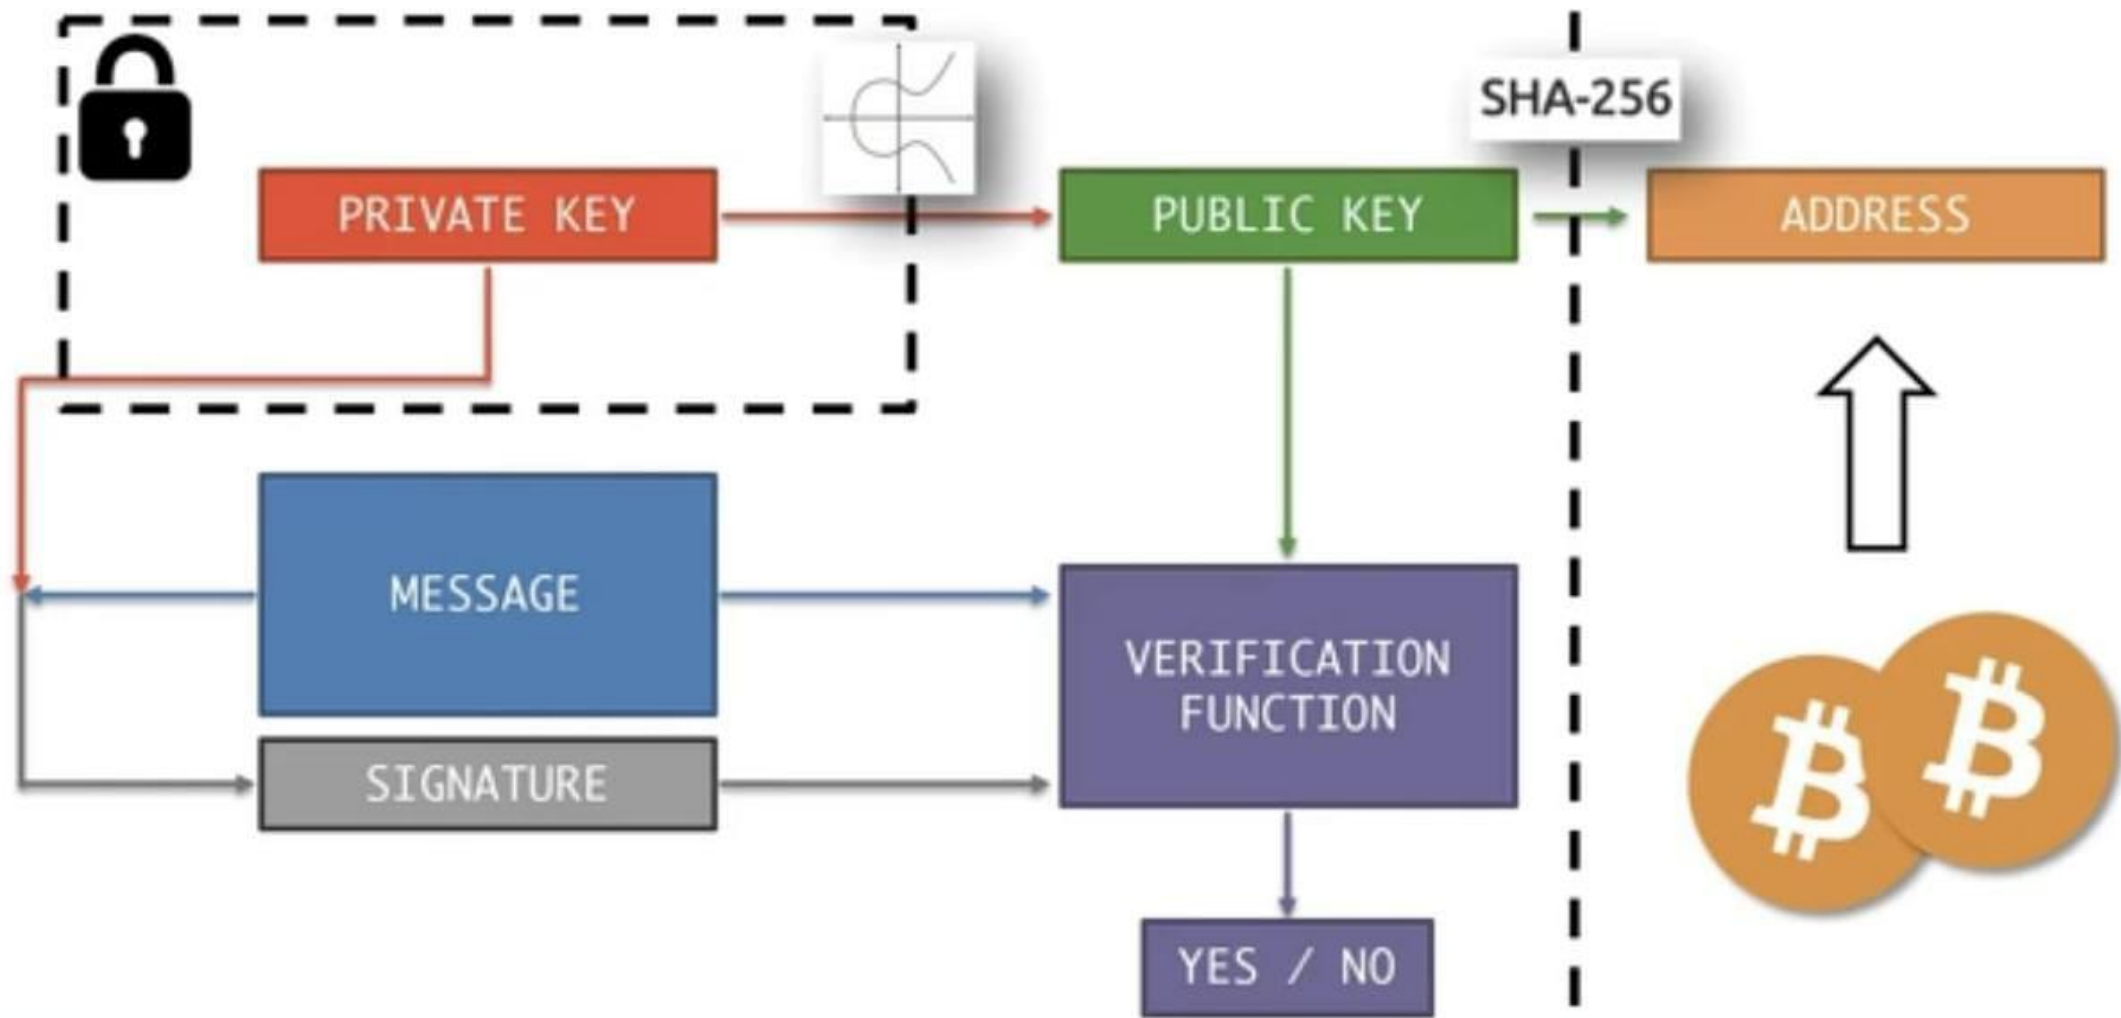

no central point of coordination

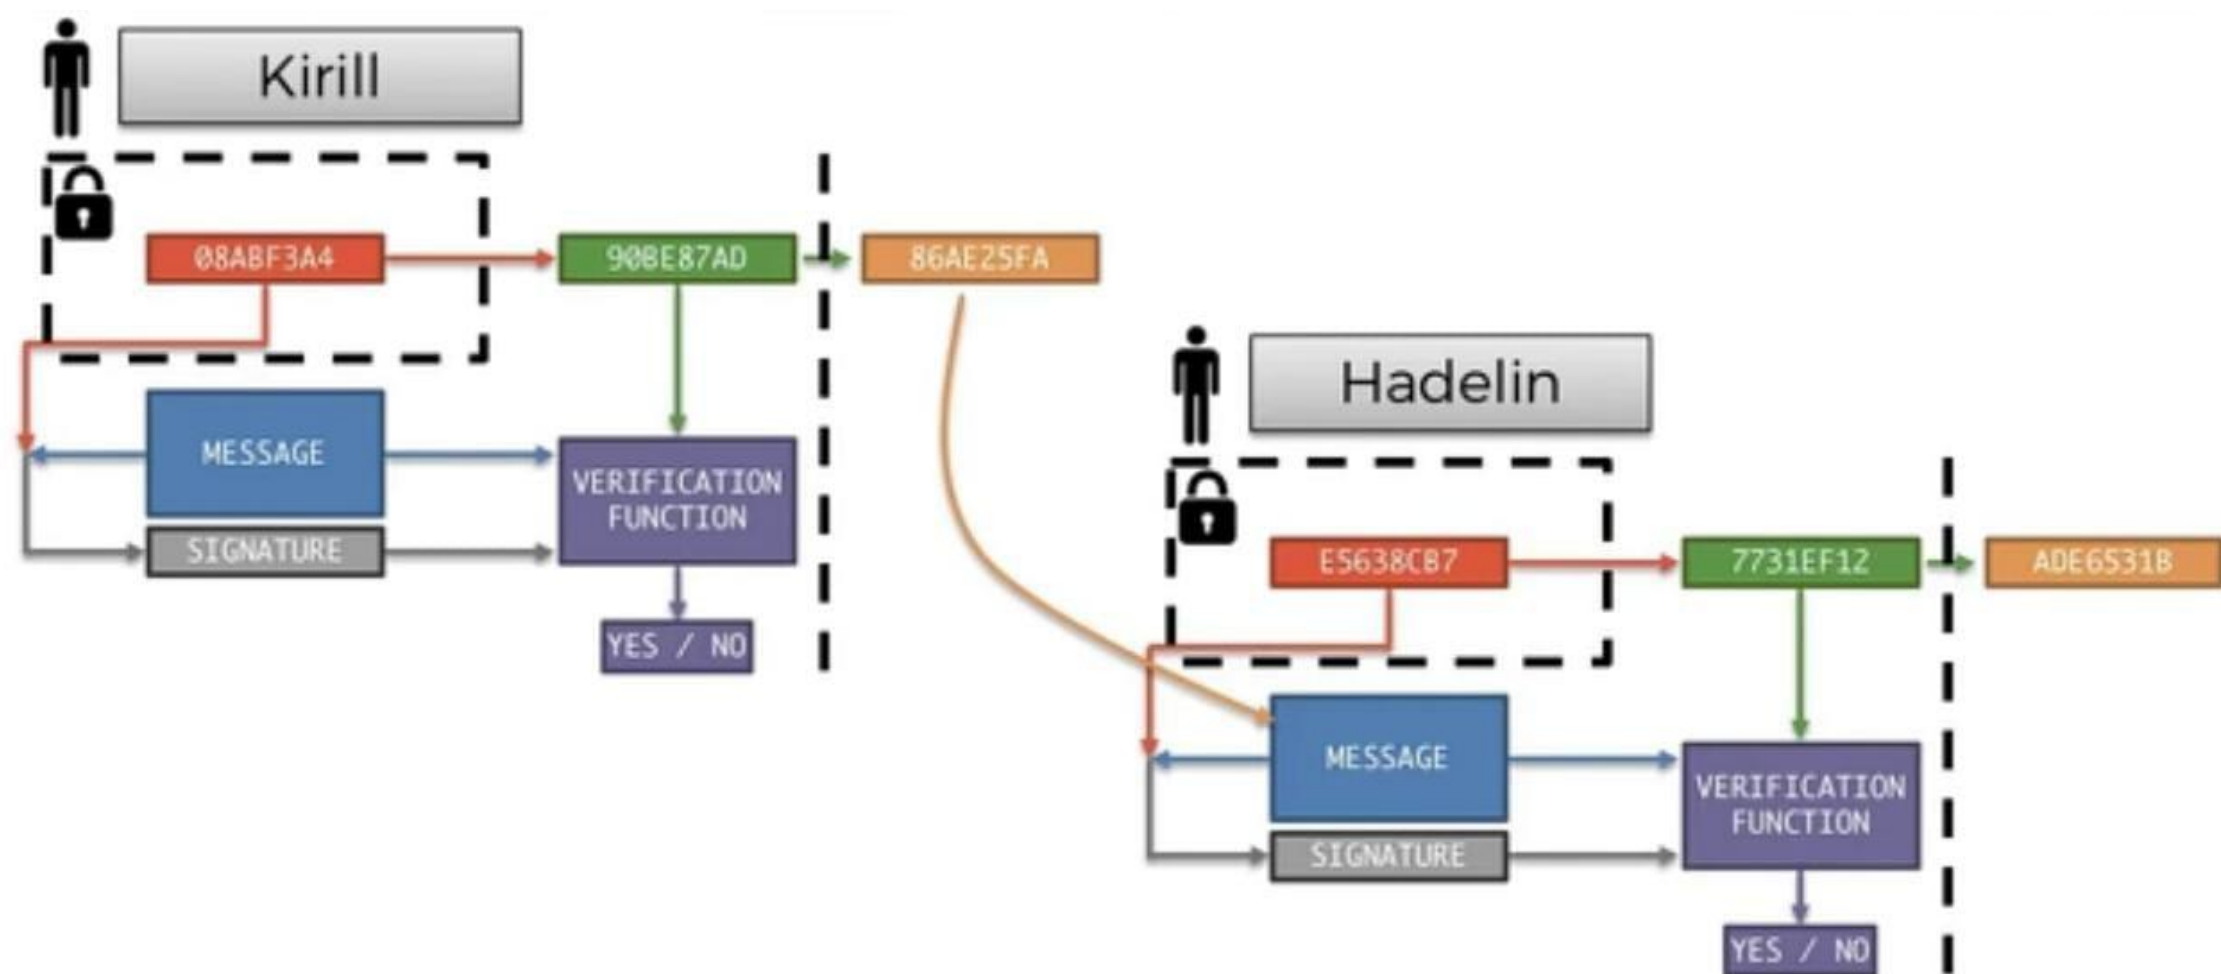

These identities are called “addresses” in Bitcoin.
